COMPUTATIONAL PATHOLOGY FROM MICROSCOPE TO SOCIAL MEDIA

Andrew J. Schaumberg, Ph.D.

Cornell University 2020

Pathologists must rapidly interpret microscopic images of a tissue specimen to provide a diagnosis. To diagnose, a pathologist may additionally consider or interpret patient history, radiology, specialized histological stains, genetic sequencing, etc. Integrating into an accurate predictive model each patient's diverse information is one of many challenges in computational pathology. This thesis' scope is computational pathology methods that seek to empower pathologists by automating tedious work, providing new capabilities, or finding similar patient cases. First, we video-recorded pathologists diagnosing at a microscope, and found deep learning could accurately predict where pathologist gaze would dwell. Such areas may be priority regions of interest for diagnosis. Second, we applied deep learning to prostate cancer whole slide images to predict if a cancerous tumor has a SPOP gene mutation. Such methods may expand the capabilities of hospitals where genomic sequencing is unavailable. Third, we integrated histological imaging and clinical information into a multimodal method to find similar patient cases across social media and notify the pathologists having these cases. Such a method brings to low-resource hospitals the subspecialty expertise of pathologists worldwide. Taken together, we conclude it is practical for such computational methods to empower pathologists on an international scale. In doing so, we were the first to predict a somatic mutation from histology images of prostate cancer, we uncovered the utility of pathology data on social media, and we devised novel methods to interpret deep learning.

# BIOGRAPHICAL SKETCH

While an undergraduate at the University of Wisconsin-Platteville [UWP], Andrew J. Schaumberg performed a 7-month work-study as a Co-op Controls Engineer at LasX Industries Inc and a 3-month research fellowship at the National Institute of Standards and Technology [NIST]. Terrie Wheeler mentored Andrew at NIST, with a project to study how the Millennial generation uses information and the NIST library for research. Because this study's survey suggested entering the same search query into many literature databases was problematic for Millennials, Andrew implemented a full-text federated search engine over open-access databases with Apache Lucene, OAI-PMH, and Ruby on Rails.

Andrew graduated from UWP with honors in 2007, with a major in Software Engineering and a minor in Mathematics. After working in software engineering and high performance computing at Cray Inc, National Jewish Health, and the US Department of Energy's Joint Genome Institute, Andrew returned to academia. He pursued a PhD in the Tri-Institutional training program in Computational Biology and Medicine, across Cornell University, Weill Cornell, and Memorial Sloan Kettering. His thesis mentor was Thomas Fuchs, and F31 grant sponsor was Mark Rubin. Andrew reunited with Terrie, who now directed Weill Cornell's library. At this time, Andrew implemented a multimodal text and image search tool over pathology cases on social media and PubMed.

Terrie transformed Weill's library to focus on study space and tools, e.g. 3D printing. Andrew learned to use the library's 3D printer, then applied these skills during the COVID-19 pandemic. At the time of this writing, he prints and freely distributes face masks to people in New York City [NYC], face shields to frontline healthcare workers in NYC, and telepathology equipment to pathologists internationally. See `http://pathobotology.org` for more information.

*In loving memory of Nestor John Grabowski, and to all patients.*

# ACKNOWLEDGEMENTS

I am grateful to many, without whom this thesis would not have been possible.

First, I would like to thank my thesis mentor Prof Thomas Fuchs for introducing me to the field of computational pathology and the diverse challenges of the field. For mentoring me closely at first, but encouraging independence by having me convince myself. For connecting me with institutional pathologists early on, and clearing the way for me to pursue social media projects, which connected me to pathologists worldwide. For teaching me deep learning techniques, while recommending simpler baseline methods for comparison. For imparting to me that statistics and quantitative analyses are not enough, that findings must "make sense".

I would like to thank my F31 grant sponsor Prof Mark Rubin for inspiring my interest in histological phenotypes of SPOP mutation in prostate cancer. For reviewing numerous slide images with me. For years of meetings, teaching me more about cancer metabolism, signal transduction, and therapeutics. For pathology-related thesis feedback. I thank Rubin lab, Xiaoai Chen, and Elizabeth Manning for extraordinary help with the grant.

I am grateful to Prof David Christini for important guidance and support. Both before I had chosen a thesis laboratory, and as my PhD progressed, I benefited from his advice whenever academic challenges arose. I am also grateful for the feedback from my committee, Prof Christina Leslie, Prof Michael Berger, and Dr Joseph Sirintrapun. I thank Prof Leslie for thesis feedback. I thank Dr Sirintrapun for taking additional time to teach me pathology at the microscope, for being there for my mentees, and for answering multifarious questions during the social media project's early stages.

I thank Prof Mariam Aly for her supervision of the social media project. For

patiently taking months to convince me to be on social media. For her human subjects research expertise, and ensuring the Institutional Review Board was in the loop before we downloaded any data. For teaching me how to communicate better on social media and with my mentees. For years of detailed feedback on my analyses, writing, and reviews. For vigorously supporting our efforts to help others affected by the pandemic, and in general making me a better person.

I am grateful to numerous pathologists worldwide, who selflessly help others through social media, including me. I thank Dr Laura Pastrían for her leadership of our project, for helping to keep everyone in contact, and for being so approachable when I was new. Dr Mario Prieto Pozuelo for fluorescence *in situ* hybridization guidance, and for being first to share cases with our project. Dr Aurélien Morini for detailed case reviews, highlighting disease state differences among images in a single social media post. Dr Bobbi Pritt for parasitology guidance. For weeks-long formative discussion among these pathologists – and Drs Nusrat Zahra, Duygu Betel Sener, Stephen Yip, Bin Xu, Srinivas Rao Annavarapu, and Kathia Rosado-Orozco – which defined our notion of "disease state" of patient cases posted to social media. Dr Jerad Gardner for later providing corroborating literature of this notion. Dr Sanjay Mukhopadhyay for a phone call that early on convinced me of the clinical importance of the "benign vs malignant" question, and for helpful feedback thereafter. Dr Olaleke Folaranmi for the importance of white balance of photomicrographs. Dr Celina Stayerman for demonstrating extraordinary attention to detail in histopathology cases, and motivating future projects. I thank all pathologist collaborators for sharing your ideas and cases. This thesis is largely built on your goodwill.

I thank my family, for patiently supporting me for decades, throughout my remote work.

# LIST OF TABLES

## CHAPTER 1

# INTRODUCTION

## 1.1 Overview and motivation

Computational pathology demands a tremendous amount of labor from many. After undergoing decades of training, a pathologist's clinical service obligations involve diagnosing potentially hundreds of patient cases daily and entering this into medical records. Additionally, laboratory staff meticulously follow protocol to prepare glass microscopy slides for pathologists, sequence genomes, and perform other tests as needed. Technicians digitally scan glass microscopy slides whole, archive glass slides, store slide images, and maintain supercomputers that run artificial-intelligence-driven computational models to process these images. Engineers continuously improve all the instruments used, ranging from the clinical laboratory to the datacenter. Informaticists conceive new computational models to gain insight into pathological processes, often using data from medical records, genomic sequencing, and whole slide images. All of this is done in the interests of the patient, who typically must take the time to come to the hospital and submit a tissue sample, in coordination with administrative staff, primary care providers, and other specialists.

It would be desirable for all this work to make the world a better place, but where might one read a plan for how to make the world a better place? We observe the United Nations' Sustainable Development Goals outline a 17-point plan to be a "blueprint to achieve a better and more sustainable future for all". Sustainable Development Goal 3: Good Health and Well-Being suggests "ensuring healthy lives and promoting the well-being at all ages is essential" and "increased access to physicians" is important[1]. To this end, it is recommended to "[s]ubstantially increase [...] the recruitment, development, training, and retention of the health workforce in developing countries" to achieve "access to quality essential health care services" for all[2]. As a way to increase access to physicians and quality health care services in general, we focus on connecting pathologists worldwide through computational pathology tools. To us, a world of connected pathologists means it is easier for pathologists to immediately obtain second opinions from other pathologists anywhere in the world. This connectivity would broaden consensus on the next steps of any patient's care, potentially confronting even the time pressures of diagnosis during surgery.

## 1.2 Research development

**Timeline and summary** Research began with a pilot study of pathologists making diagnoses at a microscope, which is detailed in chapter 2. Some chapter 2 work was repurposed to identify putative regions of interest for predicting a gene mutation in prostate cancer, which is detailed in chapter 3. This effort continues at the time of this writing. To make a more robust search/CBIR tool than was possible in chapter 3, this thesis concludes with a study of pathologists worldwide, to train an artificial intelligence [AI] that can find similar patient cases on social media (see chapter 4). A recurring challenge in these computational pathology projects is a "needle in a haystack problem". Namely, given a whole microscopy slide, it is a challenging for an AI to find a few important regions of interest to solve a problem, whether the problem is to predict the patient's disease or to predict a malignant tumor's underlying driver mutation.

### 1.2.1 Microscopy slide region of interest prediction

**Challenging for AI to identify regions of interest in a whole slide image** Computational pathology tasks often have a fundamental "needle in a haystack problem", where a patient's glass microscopy slide (i.e. the "haystack") may be summarized by a few select regions of interest (i.e. the "needle"), but the locations of these regions are not explicitly written down for an AI to know from the beginning. Moreover, a pathologist may examine multiple slides of a patient and share only one region of interest with pathologist colleagues on social media to ask for second opinions[3]. How might an AI learn to identify where regions of interest are in any slide?

**Video-recording is one of many possible ways to address challenge** Indeed, our second Strategic Aim sought to cross-reference a whole slide image with a video recording of a pathologist making a diagnosis at a microscope. If a pathologist spent more than 0.1 seconds looking at a region, then that region was deemed of interest[4][1]. In a pilot study of two pathologists for prostate and bladder cancers, we trained a Convolutional Neural Network [CNN] to accurately predict if a region is of interest to a pathologist making a diagnosis

---

[1] The assumption that pathologists will look longer at regions of interest is not without caveats. One may suggest instead pathologist need only a brief time to immediately recognize diagnostically important regions, while longer looks may indicate a pathologist's curiosity. We leave to future work comparisons of pathologist view timings and a pathologist's explicit labels of diagnostic importance.

at a microscope[4]. By separating the "needle" of the pathology from the rest of the "haystack" of the slide, downstream computational methods may be better able to (i) identify disease in slides, (ii) draw pathologist attention to regions of interest to save the pathologist time, and (iii) efficiently search through only regions of interest in large digitized whole slide libraries.

### 1.2.2 Mutation prediction from cancer histopathology

**Predicting SPOP mutation from whole slide images without pathologist intervention** The presence or absence of "driver mutations" in a patient's cancer is an alternative way to label microscopy images for an AI to learn, and this does not require a pathologist's diagnosis or video-recorded behavior. We studied the SPOP gene in prostate cancer, which is mutated in ~10% of cases[5]. Our method identified regions of interest on the basis of atypical nuclei density. For these regions we trained ensembles of CNNs to (i) predict if the SPOP gene was mutated in this patient's cancer tumor and (ii) estimate the uncertainty in this prediction, e.g. our method may estimate that a particular patient has a 33-56% chance of having an in-tumor SPOP mutation.

**Challenges in this genomic approach** However, predicting underlying mutations that drive malignant growth in a tumor is difficult because some mutations may not be histologically evident, some mutations may not be histologically distinguishable from other mutations, and some mutations may be so uncommon that machine learning is not feasible for such few patient cases. Moreover, between institutions the clinical protocols may differ in ways that fundamentally change slide appearance, e.g. microscopy slides are typically prepared as frozen sections in the TCGA patient cohort while microscopy slides are prepared as formalin-fixed paraffin-embedded [FFPE] sections in the Memorial Sloan Kettering Cancer Center patient cohort. Freezing damages and tears tissue, but this does not occur with FFPE sections. It follows that an AI trained on FFPE section slides may become inaccurate when the AI is tested on frozen section slides[5].

**Broader impacts of this work** Nonetheless, our work is widely cited by pathology-focused[6,7,8,9,10] and computationally-focused[11,12,13,14,15] literature in the field. We believe our ongoing work is the first to predict a somatic mutation in prostate cancer from H&E-stained whole slide images alone.

### 1.2.3 Connecting pathologists through patient case search

**If a patient case is challenging, find similar cases to cross-reference** In light of this priority to connect pathologists worldwide, it follows that the the grant that largely funded this research would involve *search*, which is formally referred to as “content-based image retrieval” [CBIR][3]. Our originally-proposed search method sought to find similar patient cases in The Cancer Genome Atlas [TCGA] patient cohort, given photomicrographs from a textbook or microscope. Our rationale is a pathologist considering a challenging patient case will be interested in similar patient cases, and automated *search* may find similar cases.

**Search connects pathologists who shared similar cases on social media** We later realized photomicrographs of de-identified patient cases are frequently shared by pathologists through social media and the published literature, so

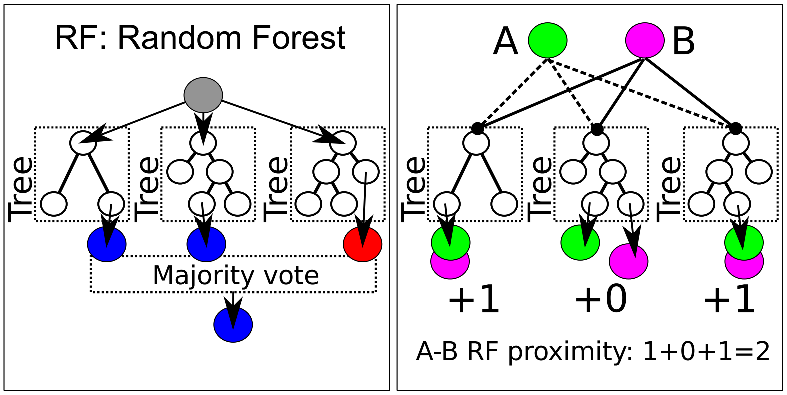

Figure 1.1: **Random Forest classification and proximity schematics.** A Random Forest [RF] consists of many Random Trees, e.g. three trees, but typically 1,000 trees are used. *At left* a RF classifies a datum (*gray circle*) according to a majority vote of the trees, e.g. two votes for the "blue class" and one vote for the "red class" means the datum is classified as "blue". Broadly, for our purposes, each datum is an image, and the Random Forest must classify the image's depicted disease state (i.e. nontumor, low grade, or malignant)[3]. *At right* an RF is reused for *search*, were two data are considered similar if they fall into the same leaf of a tree. For example, if images A and B are in the same leaf for two of the three trees in the RF, then the A-and-B RF similarity/proximity is 2.

we implemented search tools specifically for these media[16,3]. Powerfully, the connectivity of social media allows a pathologist to not only find similar cases through *search*, but also *confer* with pathologists who had similar cases. Our social-media-focused approach to has been well-received in both the search-focused[17] and pathology-focused[18,19,20] literature as our methods developed over time. Social media has offered a tractable way for us to leverage machine learning to serve, connect, and study pathologists worldwide. Ultimately, we implemented an artificial-intelligence-driven social media bot, to both find pathologists having similar cases and connect these pathologists in a conversation to discuss the next steps in a patient's care[3].

**Method interpretability suggests which features are important** Our social media bot's underlying artificial intelligence [AI] is a machine learning classifier trained to predict disease state, but this classifier is reused for search (Fig 1.1). Additionally, this classifier leverages hand-engineered features and shallow

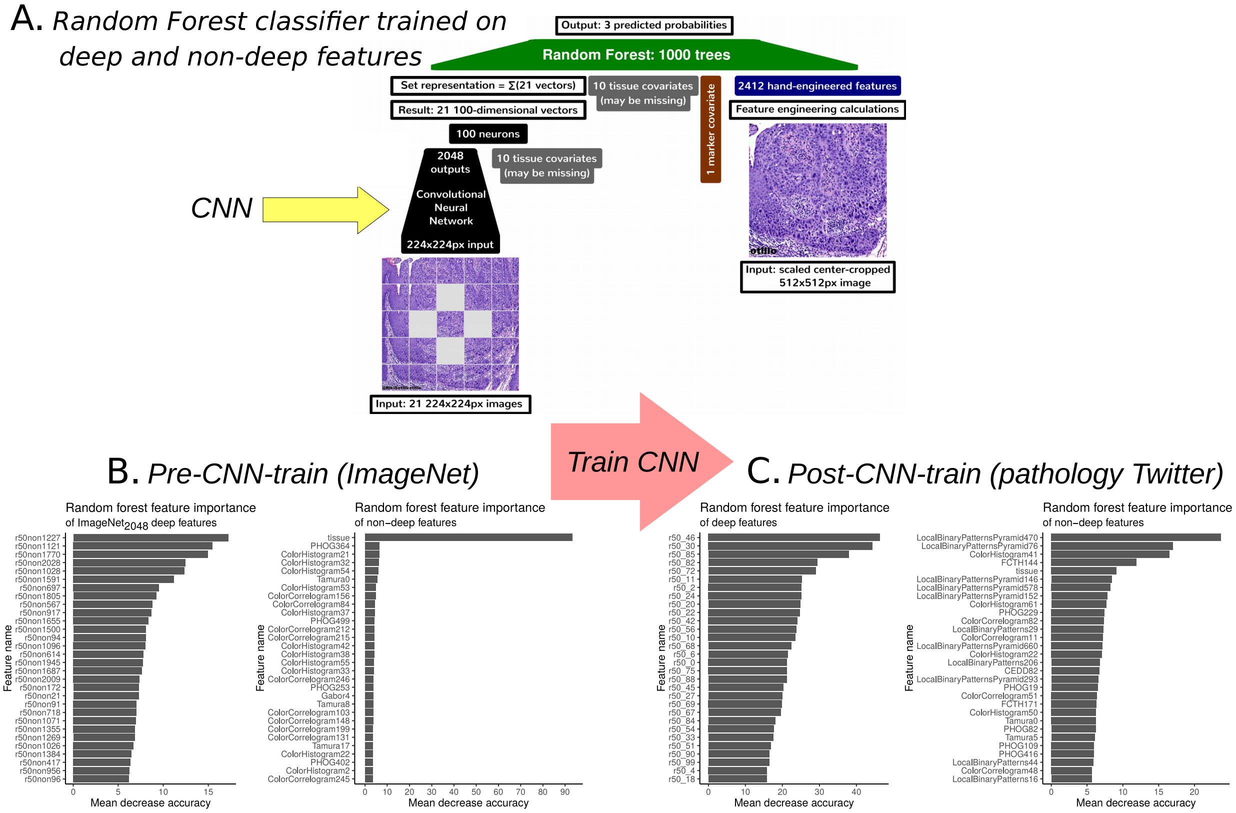

Figure 1.2: **Random Forest interpretability of deep features.** **(A)** We combine deep learning and shallow learning techniques to accurately classify disease state for patient cases posted to social media[3] (c.f. Fig 4.3). Both before **(B)** and after **(C)** training on patient case data (c.f. Figs 4.4 and S4.20, respectively), we measure Random Forest feature importance to understand what concepts the deep features from a convolutional neural network [CNN] have learned to represent. From the before-and-after changes in Random Forest feature importance one may infer what deep CNN features learned to represent from the patient case data.

learning (i.e. a Random Forest) to interpret deep learning (i.e. a Convolutional Neural Network [CNN]) features (Fig 1.2). In this way, we find tissue type (e.g. breast, dermatological, gastrointestinal, etc), color, and edge features are *less* important after CNN training. However, texture features are *more* important after CNN training. Therefore, as further explained in our recent work[3], we reason that the CNN learns histopathology-relevant edge, color, and tissue features from patient cases on social media (which reduces the importance of e.g. hand-engineered edge and color features after learning), but the deep neural network may forget histopathology-relevant texture features during learning (which increases the importance of hand-engineered texture features after learning). It "makes sense" that the CNN learns tissue type is important, e.g. infectious disease is more common in gastrointestinal tissue than breast tissue. When the concepts learned make sense broadly, one becomes confident that the AI has learned to perform a task in ways that make sense too.

## 1.3 Prevalent themes

### 1.3.1 Obtaining labeled data of sufficient quantity and diversity

For all strategic aims, we found it is challenging to obtain labeled images in sufficient quantity and diversity for accurate machine learning in computational pathology.

#### Obtaining labeled images

**Where a disease is in a slide is often not written down** Obtaining labeled images is a challenge because pathologists are often required to write down what disease is shown in a small image focused on that disease morphology. Moreover, because whole slide images are so large, the "needle in a haystack problem" arises if all that is written down is a patient's disease, without any localization of the disease in the slide. The needle in a haystack problem remains for bulk genomic sequencing, e.g. chapter 3, where a machine measures the presence or absence of a genetic mutation in a tumor, but we do not know exactly where in a slide the morphological phenotype for this mutation is evident[5].

**Crowd-source among pathologists globally to get more specifics written down** We found the most success from crowd-sourcing image labeling work across pathologists and other collaborators. For chapter 4, social media gave our project worldwide reach to collaborate with pathologists, and mentoring opportunities afforded us the help of talented High School students to curate data[3]. For chapter 2, video-recording pathologists did not disrupt the pathologist's diagnostic workflow, and we did obtain localized timing measurements for all regions throughout a whole slide image[4]. However for chapter 3, skipping a pathologist entirely by relying on genomic sequencing to label the images left us with both the aforementioned "needle in a haystack problem" and an uncertain amount of error from genomic sequencing and tumor purity[5].

**Obtaining a sufficient quantity of images**

**Patient case data in abundance on social media but even more in published case reports** For machine learning generally, more data are always better. This was especially challenging for chapter 4, because any one pathologist shares on social media several to hundreds of labeled photomicrographs, but we believed our machine learning method needed thousands to robustly predict disease state[3]. Moreover, a rare disease may only be seen by a pathologist once in their career, so we believed we needed over 100,000 photomicrographs to have any realistic chance of our search tool (i.e. pathobot) finding rare but similar patient cases. We found that making our search tool freely available and easy to use convinced many pathologists worldwide to share data with us, join our project, and become co-authors of our study. Additionally, public data from manuscripts in PubMed Central were essential to obtain over 100,000 photomicrographs, making our search tool more comprehensive. It was also challenging to filter over 1,000,000 manuscripts in PubMed Central to find over 100,0000 hemotoxylin and eosin [H&E] photomicrographs. However, our machine learning classifier trained to recognize H&E photomicrographs on social media demonstrated accurate performance and was suitable for this task.

**Video recordings provide numerous data across few patient cases** We benefited from having comprehensive pathologist timing information throughout each whole slide studied for chapter 2[4]. Deep learning could effectively be applied to these data for accurate predictions. However, the experimental approach to data collection could not be easily scaled up to many slides or multiple institutions, because a researcher had to physically meet with a pathologist to obtain video recordings. We were not aware of public data that could have further supported the deep learning task in chapter 2.

**Public and private data complementary for genomic studies** In chapter 3 we leveraged public data from TCGA, as well as private data from Memorial Sloan Kettering Cancer Center[5]. Despite the large size of these two patient cohorts and that SPOP is one of the most frequently mutated genes in prostate cancer, we still needed to request additional scans to digitize glass microscopy slides for patient cases which had our mutation of interest (i.e. SPOP). SPOP mutation occurs in ~10% of prostate cancer patient cases, so for 1000 patients only 100 typically have SPOP mutation. There are logistical challenges to involve additional private cohorts, and we are not aware of other public cohorts.

### Obtaining a sufficient diversity of images

**Patient case data from social media highly diverse** For chapter 4, the pathology images from social media are almost too diverse[3]. Pathologists may take photomicrographs with a microscope-mounted camera or smartphone. Laboratory and staining protocols differ between institutions and countries, e.g. saffron may be used in H&E sections in France[3]. Pathologists focus on different organ systems, each with their own distribution of diseases. For instance, infectious disease is more common in gastrointestinal and pulmonary tissues than neurological or breast tissues. Pathologists have different microscopes, and may illuminate their samples differently. In light of such diversity, some image normalization may be helpful, e.g. white balance correction. Importantly, such diversity among the numerous pathologists participating in a study allows computational methods to be rigorously tested through a "leave one pathologist out" cross-validation approach. Through "leave one pathologist out" testing, an AI may be trained on highly diverse data from all pathologists except one. AI performance is then tested on this one held-out pathologist's data. This procedure is repeated, with each pathologist held-out in turn for testing, and the test performance results are averaged to estimate the AI's performance in general for any pathologist.

**Video recordings across few patient cases not diverse** For chapter 2, the DeepScope data are likely not diverse enough[4]. These data came from a single institution, so it is not possible to estimate how the method performs in general across institutions. However, it was possible to estimate performance of an AI trained on one tissue (e.g. bladder cancer) tested on a different tissue (e.g. prostate cancer).

**Histopathology-genomic paired data from different patient cohorts may qualitatively differ** For chapter 3, the SPOP data are diverse in a difficult-to-compare manner[5]. TCGA data are frozen sections. Memorial Sloan Kettering Cancer Center data are FFPE sections. Therefore, when measuring performance when training on one cohort and testing on the other cohort, it may not be clear if performance changes are due to differences in sectioning protocol. Including more cohorts for a ”leave one cohort out” approach was not logistically possible.

### 1.3.2 Interaction, iteration, and multimodality matter

#### Interaction

**Interaction facilitates crowd-sourcing** Computationally, we found the most success by making tools pathologists can readily use anywhere worldwide for free[3]. Smartphones and social media are ubiquitous. The vast majority of the time, a pathologist would use our tools by mentioning “@pathobot” in a social media post, which is 10 of the maximum 280 characters in a Twitter post. This accessible user interface allowed our tools to be seamlessly embedded in the conversations of pathologists worldwide, which facilitated further recruitment of pathologists to our chapter 4 project.

**Interaction facilitates consensus** In pathology, interaction with colleagues is an important way to establish consensus. For instance, some of our pathologist collaborators reported working alone. Social media offers a way to compare one's own opinion against the opinions of other pathologists. Further, interaction allows a pathologist to use our search tools numerous times for the same patient case, including different photomicrographs, additional diagnostic terms, specific morphological descriptions, or special commands each time until the desired results are obtained.

### Iteration

**Iterate for improved performance and expanded case database** Each time a pathologist was recruited through pathobot, we curated and integrated their data into our patient case database[3]. This occurred frequently enough that we developed the Integrated Pathology Annotator [IPA] tool to help pathologists and other researchers to review the correctness of data annotations. IPA also automatically regenerates all database files for machine learning. From these updated data files an updated machine learning classifier may be trained. We believe iteratively improved classifier performance and an expanded case database served to further recruit additional pathologists, due in part to social network effects. Anecdotally, we found that some collaborating pathologists observed our rapid incremental recruitment and would recommend specific colleagues to collaborate in our study.

**Iterative consensus and search** In pathology, iteration may be an important part of establishing a diagnosis. Pathologists may use social media to not only ask for opinions to make a diagnosis, but also ask what tests should be ordered next to establish a diagnosis. This incremental winnowing of potential diagnoses from a differential diagnosis may occur though checking patient history, ordering of specific immunohistochemistry stains, etc. Iteration also allows a pathologist to use our search tools repeatedly over time as more information for the case becomes available, or as colleague opinions accumulate for context. In this way, for a specific patient case in question, the search for similar patient cases is crowd-sourced as well, across the aggregating opinions of all colleagues working together to reach consensus for this case.

### Multimodality

To diagnose, a pathologist may consider or interpret many modalities besides H&E, including patient history, radiology, gross sections, specialized histological stains, cytological smears, genomic sequencing, and other laboratory tests.

**Multimodality in ARDS, DAD, and COVID-19** For example, patient history, chest X-rays, computed tomography [CT] scans, and genetic risk factors may be considered for a clinical diagnosis of Acute Respiratory Distress Syndrome [ARDS][21]. Poor survival among patients with ARDS may make ante-mortem biopsies difficult to obtain in time for a pathological diagnosis. The histological hallmark of ARDS is Diffuse Alveolar Damage [DAD], but multiple causes of ARDS and DAD exist[21]. A polymerase chain reaction [PCR] assay on adjacent tissue blocks or nasopharyngeal swabs may elucidate specific causes of ARDS/DAD, such as COVID-19 infection[22]. For COVID-19 patients, H&E sections may indicate whether a patient died *with* COVID-19 or *from* COVID-19[23].

**Multimodality in prostate cancer** A separate example in contrast is prostate cancer, where H&E sections are more frequently available while the patient is still alive. Complementing H&E, genomic sequencing may identify both "indolent" tumors that require no further treatment and "aggressive" tumors driven by specific genetic mutations that may require precision medicine to effectively treat[24]. Though prostate cancer may be diagnosed on the basis of H&E sections, the diagnosis may be further informed by laboratory tests such as serum Prostate Specific Antigen [PSA] levels, or by IHC stains such as p63 or GATA3[24]. Further, clinical/radiological follow-up index of suspicion may be part of patient care follow-up plans[24]. Thus, in these examples, H&E-stained microscopy slides may be interpreted in the context of other modalities to establish diagnosis, guide treatment decisions, and/or determine cause of death.

**Multimodality in our methods** Indeed, a multimodal diagnostic approach is so important that pathologists often share multiple modalities in a single social media post, as reflected in our data[3]. Thus it is essential for computational pathology methods to handle multiple modalities, even if methods such as ours for chapter 4 focus on the two most common modalities: H&E and immunohistochemistry [IHC]. Our methods handle H&E explicitly, by training a machine learning classifier on H&E photomicrographs. IHC is handled as an oversimplified covariate. Additionally, our methods consider tissue type (e.g. breast, dermatological, gastrointestinal, etc), which is clinical information passed on to a pathologist. Further, our hand-engineered and natural-image-trained deep features offer a way to generically compare images in a pathology-agnostic manner. Finally, text-based matching allows patient cases with similar diagnoses (or differential diagnoses) to be matched independently of image data. We intend this multimodal approach to offer the greatest value to pathologists searching for opinions of colleagues having similar patient cases, given as much or as little information for the case as is immediately available.

## CHAPTER 2

# MICROSCOPY SLIDE REGION OF INTEREST PREDICTION FROM VIDEO RECORDINGS

Portions of this chapter first appeared in Schaumberg* et al 2017. Schaumberg et al 2016 was written in collaboration among Andrew J. Schaumberg, Peter J. Schüffler, and Thomas J. Fuchs. S. Joseph Sirintrapun and Hikmat A. Al-Ahmadie reviewed Schaumberg et al 2017. The author makes this chapter available under the terms of a Creative Commons Attribution-NonCommercial-NoDerivatives [CC-BY-NC-ND] 4.0 International license, at `https://creativecommons.org/licenses/by-nc-nd/4.0/`.

## 2.1 Scientific background

Computational pathology[25] relies on training data annotated by human experts on digital images. However, the bulk of a pathologist's daily clinical work remains manual on analog light microscopes. A noninterfering system which translates this abundance of expert knowledge at the microscope into labeled digital image data is desired.

Tracking a pathologist's viewing path along the analyzed tissue slide to detect local image saliency has been previously proposed. These approaches include whole slide images displayed on one or more monitors with an eye-tracker[26], mouse-tracker[27] or viewport-tracker[28,29] – but may suffer confounds including peripheral vision[30], head turning[31], distracting extraneous

In: Bracciali A., Caravagna G., Gilbert D., Tagliaferri R. (eds) Computational Intelligence Methods for Bioinformatics and Biostatistics. CIBB 2016. Lecture Notes in Computer Science, vol 10477. Springer, Cham

Figure 2.1: Proposed microscope-based saliency predictor pipeline workflow. The pathology session is recorded, the slide is scanned, the video frames are registered to scan patches. Lens change detection guides registration and viewing time is recorded for periods without motion. A convolutional neural net learns to classify patches as salient (long looks) or not.

detail [32], monitor resolution [33], multimonitor curvature [34], and monitor bezel field of view fragmentation [35]. Because computer customizations may potentially effect viewing times, for studies of pathologists recorded at a computer, we suggest noting the sensitivity and choice of pointing device, e.g. trackball, touch pad, touch screen, pointing stick, mouse, and if a scroll wheel or keyboard was available to zoom in or out. Only our approach does not change the pathologist's medical practice from the microscope. The microscope is a class I device appropriate for primary diagnosis according to the United States Food and Drug Administration, while whole slide imaging devices are class III [36].

In light of the confounds of alternatives, its centuries of use in pathology, and its favorable regulatory position for primary diagnosis, we believe the microscope is the gold standard for measuring image region saliency. Indeed, there is prior work annotating regions of interest at the microscope for cytology technicians to automatically position the slide for a pathologist [37].

work, these near-duplicates should be automatically detected. Duplicates may artificially inflate performance metrics.

### Disease state annotations vary in text

Our dataset is only as good as the accuracy of the hashtags and diagnoses made by the collaborating pathologists and pathologists who comment on the cases. The more pathologists that contribute to the database, the higher the risk for errors and inconsistencies. Indeed we note some uses of the #bstpath hashtag to describe breast pathology (Section S4.5.6). We should remember the fun and voluntary nature of sharing cases on social media.

While our disease state text processing algorithms take a consensus vote among the pathologists discussing the patient case, these methods are not perfect, and our manual annotations to correct this may be incomplete. We hope that by sharing our data with the community, more corrections may be made, improving the quality of our dataset.

### Disease state evidence varies in images

For our Random Forest baselines, we crop images to convert rectangular images to be uniformly square for the machine learning. However, pathologists may include diagnostic information only at the extreme edges of an image that are cropped out. A case of this from B.X. involves a hydatid cyst in the extreme right of an image, which would be cropped out. This hydatid cyst indicates *Echinococ-*

---

Case at `https://twitter.com/BinXu16/status/980404471833313280` "Kudo to @drkennethtang @luishcruzc and @DrGeeONE The answer of this case can be seen in the right corner of the 3rd picture. Dx: Echinococcus (hydatid cyst) with necrotizing pneumonia, abscess, *cus* infection, so the case is nontumoral. Our set-based deep learning approach is an incomplete remedy to this problem, where we train on 224×224px image patches sampled throughout the original image, then test using 21 224×224px patches systematically sampled throughout the original image. Although this approach samples the entire image, the remedy is incomplete in that the ground truth is not uniform throughout the image. For example, it is only based on one corner of the image that there is histological evidence of nontumor disease. It may be helpful here to use more advanced methods, which make fewer assumptions about the ground truth and allow weaker supervision, but such methods may come at a cost of requiring more data than we have currently.

### Algorithm and labeling inaccuracies

We do not expect that our text classification algorithm (Fig S4.18) perfectly interprets disease state from the text associated with an image. Moreover, we also do not expect our manual annotation process to be perfect, e.g. some stains may be incorrectly labeled as H&E, IHC, etc. We manually curate 10,000+ images, so human error as low as 1% means a handful of images are incorrectly labeled, but there could be more. By sharing our data with more pathologists and data scientists, we intend to gather feedback and correct any inaccuracies here, then measure disease state classification performance changes.

---

and granulomatous inflammation. Additional high power pictures attached."

#### No automated quality control

Finally, the size of the dataset is both a blessing and a curse. A large and diverse dataset is required to provide the most benefit to computational pathology. However, quality control for such large datasets is most feasible if done automatically, and automated quality control cannot deal with all issues. For example, some pathology images include marks designating a particular pathologist as the contributor of that image. Other pathology images have been marked by pathologists with arrows and circles. Our automated quality control pipeline enables us to rapidly discissues. For example, some pathology images include marks designating a particular pathologist as the contributor of that image. Other pathology images have been marked by pathologists with arrows and circles. Our automated quality control pipeline enables us to rapidly discriminate pathology from non-pathology images, but is not able to address these other challenges. Future steps will need to be taken for more specialized quality control.

### S4.5.18 Supplementary Future directions

#### Acquiring more data

The first step is to expand the size of this dataset by recruiting more pathologists via social media. With more data, we hope to improve performance on discriminations that were the most difficult (e.g. those involving gynecological pathology). More data may facilitate machine learning methods that discriminate between similar but less frequently used stains, such as H&E vs Diff-quik, rather than H&E vs IHC. More data might also enable us to distinguish particular organs or tissues within a histopathology tissue type, e.g. distinguish kidney tissue from bladder tissue. With increased sample size and increased tissue of origin granularity, it may be possible to predict metastatic tissue of origin. Finally, a larger dataset might also include more rare cases that can be useful for machine learning techniques that can support diagnoses.

### Expanded and specific hashtags

A second step is advocacy on social media, for (i) sharing normal tissue data, and (ii) expanded pathology hashtags. Normal tissue complements our existing "relatively unimportant" artifact and foreign body data, such as colloids and gauze, which are typically not prognostic of disease. Normal tissue also complements the description of tissue morphology in our data, if we tend to have only cancerous or diseased tissue. Separately, more descriptive hashtags may reduce our manual annotation burden, and obviate the need for us to ask pathologists to clarify what stain was used or what the tissue is. Moreover, molecular hashtags may complement the histology we see. However, we understand that for pathologists sharing cases on social media is probably a fun and voluntary activity, rather than a rigorous academic endeavor, so it may not be appropriate for us to suggest pathologists use terms from synoptic reporting in hashtag format in their Tweets. Moreover, the size of tweets is limited to 280 characters, so more than 3-4 hashtags per tweets is probably infeasible. Some pathologists are already close to this limit without using additional hashtags.

We encourage the adoption of hashtags that explicitly identify what stains or techniques are used (this is not an exhaustive list):

1. #he indicates there are one or more H&E-stained images in the tweets.
2. #ihc indicates there are one or more IHC-stained images in the tweets.
3. #pas indicates there are one or more periodic acid-Schiff images in the tweets.
4. #diffq indicates there are one or more diff-quik images in the tweets. There is a common misspelling of diff-quick, so our hashtag avoids this misspelling.
5. #gross indicates one or more gross section images are in the tweets. This is typically fresh cut tissue, e.g. an entire excised tumor or a large piece of an organ.
6. #macro indicates an unmagnified picture of a microscopy slide. Unfortunately, such pictures are occasionally referred to as gross.
7. #endo indicates one or more endoscopy images are in the tweets.
8. #ct indicates one or more CT scan images are in the tweets.
9. #xray indicates one or more X-ray images are in the tweets.

We encourage hashtags to describe not only the histological features of a case, but also the molecular features of a case. Again, this hashtag list is far from exhaustive.

1. #braf indicates the BRAF gene is known to be mutated, perhaps through sequencing.
2. #msi indicates micro-satellite instability, which again may be evident from sequencing.
3. #desmin indicates that the IHC used targets desmin.

We encourage the adoption of hashtags that explicitly identify any artifacts, art, or pathologist annotations/marks on the image.

1. #artifact or #artefact indicates there are artifacts or foreign bodies in one or more images, such as colloids, barium, sutures, Spongostan$^{TM}$, gauze, etc. We encourage the tweets message text to identify what the artifact or foreign body is.
2. #pathart is a hashtag in use today, but unfortunately it is used in two ways: (i) to identify naturally-occurring and unmodified pathology images that are "pretty" or "interesting" as natural works of art, and (ii) to identify images that have been modified by the pathologist herself/himself to be "funny" or "interesting". The trouble is (i) is "acceptable" pathology for analysis while (ii) is not. We advocate for the continued use of the #pathart hashtag, but with clarification, below:
3. #drawn or #annotated indicates the pathologist made hand-drawn marks on one or more images, such as arrows, circles, or artistic manipulations. Artistic manipulations may include drawing exclamation points, question marks, eyes, mouths, faces, skulls, cartoon bodies, etc on the image. So, "#pathart #drawn" is likely a pathology image with artistic drawn marks that prevents the image from being an "acceptable" pathology image for analysis, while "#pathart" without "#drawn" is likely a pathology image that is a naturally occurring unmodified histology image that is an "acceptable" pathology image for analysis.
4. Alternatively, "#pathfun" or "#pathdrawing" may refer artistically manipulated pathology pictures, leaving "#pathart" exclusively for naturally-occurring pathology that are "pretty" or "interesting" from an artistic per-

spective.

We encourage the adoption of hashtags that give other information about the image.

1. #pathbug is an existing hashtag that indicates a parasite or other co-occurring non-human organism is depicted in one or more images in the tweets. The #parasite tag is sometimes used instead.
2. #panel indicates one or more multi-panel images are in the tweets.

We encourage all adopted pathology-related hashtags to be registered in an ontology, e.g. `https://www.symplur.com/healthcare-hashtags/ontology/pathology/`. A hashtag ontology can standardize the hashtags used, which in turn can (i) help pathologists in the same subspecialty find each other, and (ii) simplify computational analyses of hashtag text.

# CHAPTER 5

# CONCLUSION

**Deep learning and whole slide images are staples in computational pathology** Computational pathology studies often apply deep learning to whole slide images, with applications including classification, detection, and segmentation[11]. Indeed, we similarly apply deep learning to whole slide images in chapter 2 and chapter 3. Whole slide images are high-quality micrographs, which are amenable for deep learning, and other automated analyses.

**Deep learning's performance strengths demand ample data** Deep learning excels at processing large amounts of raw data[151], which is both a strength and a weakness in computational pathology. Strong performance is possible without human-guided feature engineering, because the deep neural network can in a data-driven manner learn patterns from the raw data. A weakness is that strong performance often requires large amounts of diverse data, e.g. the ImageNet dataset has over 14 million images[51]. Datasets of this scale and diversity may not be readily available in most computational pathology studies.

**Data demands in light of pathology's multimodal and multi-tissue nature** To reduce the amount of data needed for deep learning to achieve acceptable performance, computational pathology studies often use pre-trained deep neural networks (i.e. "transfer learning"[3,4,5]), focus on a specific data modality (e.g. H&E, chest X-ray, etc), and focus on one specific tissue at a time (brain, breast, etc)[11]. Such focused study may not reflect a pathologist's multimodal approach to diagnosis in practice, which may consider together patient history, radiology, H&E, etc for a variety of tissues[21,24]. Restated, a pathologist may be expected to both consider multiple data modalities to render a single diagnosis, and for many different tissues accurately diagnose the full range of diseases from infection to malignancy. In contrast, often a single deep-learning-based classifier for computational pathology may only work with a single data modality and single tissue type[11]. Encouragingly however, there are recent developments in *multi-tissue* cancer-specific H&E-specific computational methods for whole slide images, where regions of interest are randomly-sampled[152] or pathologist-sampled[153]. As described in chapter 4, a recent method of ours is multi-tissue, pan-disease (i.e. all diseases from infection to malignancy), and multimodal (H&E with covariates for tissue type and marker stains e.g. IHC) for pathologist-sampled regions of interest[3].

**Crowd-sourcing makes data annotation and curation tractable** We applied a form of crowd-sourcing to address the challenge of obtaining a sufficiently large, diverse, and multimodal dataset for deep learning in computational pathology[3]. Specifically, we found the most success in respectfully asking pathologists worldwide to collaborate with us, according to protocols approved by an Institutional Review Board [IRB]. When we needed data, we asked pathologists. When we needed ideas, we asked pathologists. As more pathologists collaborated with us, our pathology data and pathologist interactions became more diverse and widely distributed. The hashtags and brevity encouraged by social media kept text annotations of photomicrographs simple, facilitating simple text analysis methods to determine ground truth labels for images. We avoided the "needle in a haystack problem", because pathologists would typically share regions of interest, rather than whole slide images. A caveat with our approach is that we manually curate each patient case from social media, which is a time-consuming. We shared this curation task with other students, to partially mitigate the time cost.

**Future directions** Whole slide images offer a complementary future direction, now that we have established methods for regions of interest[3]. Publicly available patient cohorts of whole slide images, like TCGA, offer whole exome sequencing data that are uncommon to find even summarized on social media. With some adaptation, we believe the global reach of our social media tools[3] may increase the impact of our mutation prediction tools[5]. Through social media, we may potentially add mutation prediction capabilities to hospitals worldwide where genomic sequencing is unavailable. Moreover, we found leveraging public data, e.g. H&E photomicrographs in published case reports available in PubMed Central, to qualitatively improve the utility of our patient case search tools[3]. Such published case reports offer a depth of analysis that is not possible to fully express in brief social media posts. We look forward to working with others to grow our nascent project, to connect pathologists worldwide and improve patient well-being, according to United Nations goals.
